1 Purpose

This technical specification specifies neutron and gamma irradiation tests and associated services to assess the performance and reliability of a prototype In-Vessel Coil (IVC) conductor. The Contractor shall be in charge of the definition of a time and cost effective irradiation test program to be reviewed by ITER, if approved, be responsible for all aspects of its implementation including quality assurance, design, manufacturing, and conduct and report the results from the irradiation tests.

A key component of the IVC conductor is the mineral insulation which consists of compressed MgO powder. The insulation provides three main functions, namely structural support of the copper conductor, thermal conduction between the stainless steel jacket and the copper conductor, and electrical insulation between the stainless steel jacket and copper conductor. The latter two functions depend on properties of the MgO which are known to be affected by radiation flux and fluence.

Although prior research has addressed these effects, the results are known to be highly dependent on the composition of the MgO (grain size, compaction, impurity content) as well as the spectrum of flux and fluence.

The purpose of the tests described here is to characterize the radiation effects on the insulator, nominally MgO, as formulated and integrated into the planned Mineral Insulated Conductor (MIC) configuration under irradiation test conditions which simulate conditions in the ITER fusion reactor. This specification provides a description of the test samples, test procedures, and measurements which are required to characterize the behaviour of the MIC in a radiation field so that the assumptions used in the design process can be confirmed and/or refined.

CONDUCTOR: In this document, the term conductor is used for the part formed of a tube of copper, insulated by mineral, inserted into a metal jacket and compacted.

3 Background

3.1 ITER In-Vessel Coils

ITER is project now underway in France to construct a device that will demonstrate nuclear fusion power at a power plant relevant scale. ITER relies on magnetic confinement of a deuterium–tritium plasma to achieve thermonuclear conditions. The main components of the magnetic field are supplied by superconducting coils located outside the ITER vacuum vessel. However, a set of in-vessel coils (IVCs) is required to make local adjustments to the field on a fast time scale.

ITER is incorporating two types of In-Vessel Coils (IVCs): ELM Coils to mitigate Edge Localized Modes and VS Coils to provide Vertical Stabilization of the plasma. The ELM coils consist of three (upper, midplane, and lower) 6-turn rectangular “picture frame coils”, for a total of 27 coils. The VS coils consist of one upper and one lower 4-turn solenoidal “ring” coil connected in an anti-series “saddle” arrangement. Strong coupling with the plasma is required so that the ELM and VS Coils can meet their performance requirements. Accordingly, the IVCs are in close proximity to the plasma, mounted in between the blanket shield modules and the vacuum vessel. All IVCs are supported via bolts to the rails which are welded to the VV wall. This location leads to difficult integration with diagnostics and cooling water manifolds, and results in a radiation and temperature environment that is severe necessitating new solutions for material selection as well as challenging analysis and design solutions.

Figure 1: Overview of the IVCs inside the machine
3.2 IVC Conductor

The in-vessel environment is severe, characterized by large transient electromagnetic fields, high radiation flux, and high temperature. To withstand this environment and provide the required functionality a “mineral insulated conductor” (MIC) technology has been selected for the IVC conductor \([i]\). A key component of the MIC is the mineral insulation which will consist of compressed MgO powder. The insulation provides three main functions, namely structural support of the copper conductor, thermal conduction between the stainless steel jacket and the copper conductor, and electrical insulation between the stainless steel jacket and copper conductor. The latter two functions depend on properties of the MgO which are known to be affected by radiation flux and fluence \([ii]\). Although prior research has addressed these effects, the results are known to be highly dependent on the composition of the MgO (grain size, compaction, impurity content) as well as the neutron flux spectrum and fluence. Figure 2 shows the MIC configuration, consisting of an axially water-cooled (through the hollow centre) copper conductor surrounded by mineral insulation and a stainless steel jacket.

Cross-section of the Mineral-Insulated Conductor for ITER ELM and VS in-vessel coils is as shown in Figure 3. Geometry and materials are listed in Table 1.

4 Technical requirements

4.1 Contractor’s capabilities

To perform the irradiation tests, the Contractor shall have access and the capacity to conduct irradiation tests in neutron and gamma irradiation facilities, including post-irradiation examination activities which require a hot-cell facility. Experience in designing complex in-situ irradiation tests including on-line measurement capabilities with control of temperature and vacuum during the irradiation test is essential. The Contractor shall have the capacity to conduct radiation damage analysis (transmutation, gas production, displacement per atom, dose rate), mainly for neutron irradiated materials and shall have an access to specific expertise in assessing radiation-induced degradation of material properties (electrical, mechanical, thermal, outgassing) in various types of irradiated materials, such as ceramics, insulators, etc.

This Contract aims to assess, through dedicated Irradiation Tests and specific radiation effect expert studies, radiation-induced degradations of physical properties in a Mineral Insulated Conductor.

As a minimum requirement the Contractor shall have practical knowledge and understanding of gamma and neutron radiation effects on insulator materials with a particular emphasis for
magnesium oxide materials and the following effects: Effect of irradiation on electrical breakdown; RIED, RIC, RITES, RIEMF, TIEMF, RITCL, neutron induced structural changes.

The Contractor shall have an access (including license) to the software package needed to conduct the radiation testing activities, i.e. software packages where applicable for:
- Ionising dose calculation
- Design including CAD work
- Data acquisition
- Data processing.

The Contractor shall have an access to nuclear radiation software/codes and nuclear cross-section libraries for both fission and fusion applications. The Contractor shall write, where required, the codes/scripts to run the software.

**4.2 Irradiation conditions**

Peak irradiation conditions that IVC would receive during ITER operation at full fusion power of 500 MW are given in Table 2. It is expected the irradiation tests will be able to replicate the effect of radiation from the ITER fusion plasma. The characteristics of the source shall be evaluated by the Contractor to determine the appropriate choice of sample locations, flux level, and test duration to offer the best compromise between irradiation time and requirements of this specification. The Contractor shall characterize the irradiation conditions of the irradiation channel by providing the neutron energy spectrum (n/cm$^2$/s) and nuclear heating (in Gy/s) preferentially based on dosimetry measurements, or alternatively through radiation transport analysis. The neutron and gamma flux and spectrum will be determined by the characteristics of the test source as well as the ability to place the samples at a particular distance from the source behind objects (either part of the facility or added to the test chamber) which would influence the energy of the particles incident on the samples.
